Gluon-Async: A Bulk-Asynchronous System for Distributed and Heterogeneous Graph Analytics

University of Texas at Austin

Abstract—Distributed graph analytics systems for CPUs, like D-Galois and Gemini, and for GPUs, like D-IrGL and Lux, use a bulk-synchronous parallel (BSP) programming and execution model. BSP permits bulk-communication and uses large messages which are supported efficiently by current message transport layers, but bulk-synchronization can exacerbate the performance impact of load imbalance because a round cannot be completed until every host has completed that round. Asynchronous distributed graph analytics systems circumvent this problem by permitting hosts to make progress at their own pace, but existing systems either use global locks and send small messages or send large messages but do not support general partitioning policies such as vertex-cuts. Consequently, they perform substantially worse than bulk-synchronous systems. Moreover, none of their programming or execution models can be easily adapted for heterogeneous devices like GPUs.

In this paper, we design and implement a lock-free, non-blocking, bulk-asynchronous runtime called Gluon-Async for distributed and heterogeneous graph analytics. The runtime supports any partitioning policy and uses bulk-communication. We present the bulk-asynchronous parallel (BASP) model which allows the programmer to utilize the runtime by specifying only the abstract communication required. Applications written in this model are compared with the BSP programs written using (1) D-Galois and D-IrGL, the state-of-the-art distributed graph analytics systems (which are bulk-synchronous) for CPUs and GPUs, respectively, and (2) Lux, another (bulk-synchronous) distributed GPU graph analytical system. Our evaluation shows that programs written using BASP-style execution are on average \(1.5\times\) faster than those in D-Galois and D-IrGL on real-world large-diameter graphs at scale. They are also on average \(12\times\) faster than Lux. To the best of our knowledge, Gluon-Async is the first asynchronous distributed GPU graph analytics system.

Index Terms—Graph analytics, distributed and heterogeneous, BSP model, asynchronous parallel execution models.

I. INTRODUCTION

Present-day graph analytics systems have to handle large graphs with billions of nodes and trillions of edges [1]. Since graphs of this size may not fit in the main memory of a single machine, systems like Pregel [2], PowerGraph [3], Gemini [4], D-Galois [5], D-IrGL [5], and Lux [6] use distributed-memory clusters. In these distributed graph analytics systems, the graph is partitioned [7], [8], [9] so that each partition fits in the memory of one host in the cluster, and the bulk-synchronous parallel (BSP) programming model [10] is used. In this model, the program is executed in rounds, and each round consists of computation followed by communication. In the computation phase, each host updates node labels in its partition. In the communication phase, boundary node labels are reconciled so all hosts have a consistent view of labels. The algorithm terminates when a round is performed in which no label is updated on any host.

One drawback of the BSP model is that it can exacerbate the performance impact of load imbalance because a round cannot be completed until every host has completed that round. This happens frequently in graph analytics applications for two reasons: (1) unstructured power-law graphs are difficult to partition evenly, and (2) efficient graph analytics algorithms are data-driven algorithms that may update different subsets of nodes in each round [11], making static load balancing difficult.

One solution is to use asynchronous programming models and systems [12], [13], [14], [15], [16], [17], which take advantage of the fact that many graph analytics algorithms are robust to stale reads. Here, the notion of rounds is eliminated, and a host performs computation at its own pace while an underlying messaging system ingests messages from remote hosts and incorporates boundary node label updates into the local partition of the graph. Asynchronous algorithms for particular problems like single-source shortest-path (sssp) [18] and graph coloring [19] have also been implemented. Some of these systems or implementations use global locks or send small messages, but current communication substrates in large clusters are engineered for large message sizes. The other systems send large messages but either do not handle general partitioning policies like vertex-cuts [20], [21] or do not optimize communication [5]. Consequently, the performance of these systems is not competitive with BSP systems like Gemini [4] or D-Galois [5]. In addition, it is not straightforward to extend these asynchronous programming or execution models to execute on heterogeneous devices like GPUs.

In this paper, we explore a novel lock-free, non-blocking, asynchronous programming model that we call bulk-asynchronous parallel (BASP), which aims to combine the advantages of bulk communication in BSP models with the computational progress advantages of asynchronous models. BASP retains the notion of a round, but a host is not required to...
A. Overview of Bulk-Synchronous Parallel (BSP) Execution

At the start of the computation, the graph is partitioned among the hosts using one of many partitioning policies [20]. Figure 1 shows a graph that has been partitioned between two hosts. The edges of the graph are partitioned between hosts, and proxy nodes are created on each host for the endpoints of its edges. Since the edges connected to a given vertex may be mapped to different hosts, a given vertex in the graph may have proxies on several hosts. One of these proxies is designated the master, and the others are designated as mirrors. During computation, the master holds the canonical value of the vertex, and it communicates that value to the mirrors when needed. In Figure 1, host $h_1$ has masters for nodes $\{A,B,E,F,I\}$ and mirrors for nodes $\{C,G,J\}$.

Execution of the program occurs in rounds. In each round, a host computes independently on its partition of the graph. Most existing systems use the vertex programming model in which nodes either update the labels of their neighbors (push-style operator) or update their own labels using the labels of their neighbors (pull-style operator) until quiescence is reached. Since a vertex in the original graph can have proxies on several hosts, the labels of these proxies may be updated differently on different hosts. For example, in a push-style breadth-first search (BFS) computation on the graph of Figure 1 rooted at vertex A, the mirror vertex for G on host $h_1$ may get the label 2 from B while the master vertex for G on host $h_2$ remains at the initial value $\infty$.

To reconcile these differences, it is necessary to perform inter-host communication. A key property of many graph analytics algorithms is that the differences among the labels of vertices can be reconciled by communicating the labels of all mirrors to the master, reducing them using an application-dependent operation, and broadcasting the result to all mirrors (as each edge is present on only one host, updates to edge labels do not involve communication). In the BFS example considered above, the value 2 will be sent to the master for vertex G on host $h_2$ where it is reduced with the master’s label using the “minimum” operation, and the result 2 is used to update the labels of the master and mirrors. This pattern of reconciling labels using a reduction operation at the master followed by broadcast to mirrors can be used for any partitioning strategy [5]. It can also be used to offload the computation on any device [5].

In the BSP model, this reconciliation of node labels by inter-host communication is performed in each round of execution, and a host must send and ingest all updates from other hosts in that round before it can proceed to the next round. As a consequence, the slowest, or straggler, host in a round deter-

} while (terminator.cannot_terminate());

B. Overview of Bulk-Asynchronous Parallel (BASP) Execution

The bulk-asynchronous parallel (BASP) execution model is based on the following intuition: when a host completes its computation in a round, it can send messages to other hosts and ingest messages from other hosts, but it can go on to the next round of computation without waiting for messages from any stragglers. Conceptually, the barrier at the end of each BSP round becomes a point at which each host sends and ingests messages without waiting for all other hosts to reach that point. The correctness of this execution strategy depends on the fact that graph analytics algorithms are resilient to stale reads: as long as there are no lost updates, execution will complete correctly.

Since hosts perform communication only at the end of a round, the BASP execution model permits the message transport layer to use large messages, which is advantageous on current systems since they do not handle small messages efficiently. In contrast, the asynchronous model in GraphLab [12] uses small messages (along with locks) to interleave inter-host communication with computation, which is difficult to support efficiently on current systems.

Figure 2(a) shows a timeline for BSP-style computation on two GPUs. Each GPU is assumed to be a device that is connected to a host that performs inter-host communication. In each round, a GPU performs computation, transfers data to its host, and gets data from its host when that host receives it from the remote host. One feature of efficient graph analytics algorithms is that the amount of computation in each round in a given partition can vary unpredictably between rounds, so balancing computational load statically is difficult. This means that in each BSP round, some GPUs may be idle for long periods of time waiting for overloaded GPUs to catch up. This is shown in the second BSP round in Figure 2(a): device H1 has more computation to do than device H0 in some rounds (and vice-versa), so in those rounds, one host must idle or wait for the other host to finish and send its data. Figure 2(b) illustrates the same computation under the BASP-model: here, the idle time has been completely eliminated.

While BASP exploits the resilience of graph analytics programs to stale reads to compensate for lack of load balance, stale reads may result in wasted computation. For example, under BSP execution, a host may ingest an update from another host and compute immediately with that value in the next round, whereas under BASP execution, the host may miss the update, compute with the stale value, and see the update only in a later round at which point it will need to repeat the computation with the updated value. Therefore, if load is already well-balanced under BSP execution, BASP
execution may not be advantageous. We study these trade-offs by building and analyzing a BASP system.

III. ADAPTING BULK-SYNCHRONOUS SYSTEMS FOR BULK-ASYNCHRONOUS EXECUTION

In this section, we describe how we adapted a BSP-style distributed and heterogeneous graph analytics system for BASP execution using the state-of-the-art communication substrate Gluon [5]. We first describe the changes required to Gluon application programs to make them amenable to BASP execution (Section III-A). We then describe changes to Gluon to support BASP-style execution (Section III-B). We use the terms Gluon-Sync and Gluon-Async to denote BSP-style and BASP-style Gluon, respectively. Finally, we present a non-blocking termination detection algorithm that is required for BASP-style execution (Section III-C). Based on our experience, we believe that other BSP systems can also be easily adapted to BASP.

A. Bulk-Asynchronous Programs

D-Galois [5] is the state-of-the-art distributed graph analytical system for CPUs. D-Galois programs are shared-memory Galois [23] programs that make calls to the Gluon-Sync communication substrate to synchronize distributed-memory computation. Figure 3 shows a code snippet for single-source-shortest-path (sssp) application. Each host processes its partition of the graph in rounds; computation is followed by communication. The compute phase (shown at Line 24) processes the vertices in the partitioned graph using a push-style operator (shown at Line 9) to compute and update the new distance values for their neighbors. The communication phase uses Gluon’s communication interface, i.e., the sync() method (shown at Line 25). Gluon is responsible for coordinating the communication among all hosts; at the end of this phase, all hosts have a consistent view of node labels. The application terminates when there is a round in which no host updates a node label. This can be detected using Gluon’s distributed accumulator to determine the number of updates among all hosts in a round.

Figure 4 shows the same sssp application in the BASP programming model using Gluon-Async. The changes to the application are highlighted. The try_sync (non-blocking) call is responsible for coordinating the communication of labels among the hosts asynchronously. It ensures that each host eventually receives all the expected messages; in other words, it ensures that the hosts have a consistent view of node labels eventually. However, the challenge for each host then is to detect the termination of an application. This is handled efficiently using the cannot_terminate() method. The cannot_terminate (non-blocking) call is responsible for terminating if and only if no node labels can be updated on any host1. It ensures that no host terminates as long as some host has some computation or communication left to be completed.

1The value set to DistTerminator on each host determines whether “no node labels are updated” or another quiescence condition is the termination criteria.

Since try_sync() and cannot_terminate() methods are non-blocking in nature, a host that performs synchronization can proceed to next round of computation phase without waiting for the communication process to complete. Thus, it may improve the performance.

While we explain these changes using D-Galois, the changes to other Gluon-based systems are similar because the only lines of code that changed are those related to Gluon. For example, in D-IrGL, the state-of-the-art distributed GPU graph analytical system, an IrGL compiler-generated CUDA kernel is called instead of galois::do_all, and the sync structures have CUDA kernels instead of CPU code. None of this needs to be changed to make the program amenable to BASP execution.

All programs that can be run asynchronously in existing distributed graph frameworks like PowerSwitch [14] and GRAPE+ [17] can use BASP. In addition, if a program can be run asynchronously in shared-memory, then it can use BASP on distributed-memory. In shared-memory, BSP programs can be made asynchronous if the program is resilient to stale reads and if computation is independent of the BSP round number. The same condition acts as a pre-requisite for changing BSP programs to BASP programs. For example, betweenness centrality [24] uses round number in its computation and requires BSP-style execution for correctness, so it cannot be changed for BASP-style execution. Most other BSP graph programs that have been used in the evaluation of distributed graph processing systems [3], [4], [5], [6], [22] can be changed to BASP-style execution by changing only a few lines of code.

B. Bulk-Asynchronous Communication

Recall from Section II that algorithm execution in both Gluon-Sync and Gluon-Async is done in local rounds where each round performs bulk-computation followed by bulk-communication. The bulk-communication itself involves a reduce phase followed by a broadcast phase. Thus, each round has 3 phases: computation, reduce, and broadcast. The computation phase is identical in Gluon-Sync and Gluon-Async, but the other phases differ.

The reduce and broadcast phases are blocking in Gluon-Sync and non-blocking in Gluon-Async. In Gluon-Sync, hosts exchange messages in each phase (even if the message is empty) and hosts wait to receive these messages; this acts like an implicit barrier. Messages are sent in the reduce or broadcast phase of Gluon-Async only if there are updates to mirror nodes (empty messages are not required due to relaxation of synchronization barriers) and no host waits to receive a message. The action for the received messages in Gluon-Async depend on whether they were sent in the reduce or broadcast phase. As there are two phases and messages could be delivered out-of-order, we distinguish between messages sent in reduce and broadcast phases using tags. We describe this more concretely next.

Let host $h_i$ have the set of mirror proxies $P_i$ for which the set of master proxies $P_{a_i}$ are on host $h_{a_i}$. Let $U_i$ be the set of mirror proxies on $h_i$ that are updated in round $r$ (by
definition, \( U_i \subseteq P_h \). Let \( U_a \) be the master proxies on \( h_a \) that are updated in round \( r \), during either computation or reduce phases (by definition, \( U_a \subseteq P_h \)).

In Gluon-Sync, the Gluon substrate performs the following operations for every pair of \( h_i \) and \( h_a \):

- **Reduce phase for \( h_i \):** Sends one message \( m_R \) containing values of \( U_i \) to \( h_a \) (if \( U_i = \emptyset \), then an empty message is sent) and resets the values of \( U_i \) to the identity element of the reduction operation.
- **Reduce phase for \( h_a \):** Waits to receive \( m_R \) from \( h_i \) and, once received, uses the reduction operator and the values in \( m_R \) to update the corresponding master proxies in \( P_a \).
- **Broadcast phase for \( h_a \):** Sends one message \( m_B \) containing values of \( U_a \) to \( h_i \) (if \( U_a = \emptyset \), then an empty message is sent).
- **Broadcast phase for \( h_i \):** Waits to receive \( m_B \) from \( h_a \) and, once received, uses the values in \( m_B \) to set the corresponding mirror proxies in \( P_i \).

To support BASP-style execution of Gluon-Async, we modified the Gluon communication-optimizing substrate to perform the following operations (instead of the above) for every pair of \( h_i \) and \( h_a \):

- **Reduce phase for \( h_i \):** If \( U_i \neq \emptyset \), sends a reduce-tagged message \( m_R \) containing values of \( U_i \) to \( h_a \) and resets the values of \( U_i \) to the identity element of the reduction operation.
- **Reduce phase for \( h_a \):** For every reduced-tagged message \( m_R \) received from \( h_i \), uses the reduction operator and the values in \( m_R \) to update the corresponding master proxies in \( P_a \).
- **Broadcast phase for \( h_a \):** If \( U_a \neq \emptyset \), sends a broadcast-tagged message \( m_B \) containing values of \( U_a \) to \( h_i \).
- **Broadcast phase for \( h_i \):** For every broadcast-tagged message \( m_B \) received from \( h_a \), uses the reduction operator and the values in \( m_B \) to update the corresponding mirror proxies in \( P_i \).

If the reduction operator is not used in the broadcast phase of Gluon-Async, algorithms may not yield correct results (or even converge). To illustrate this with an example, we show the synchronization of proxies in Figure 5 for the single-source shortest path (sssp) code in Gluon-Async (shown in Figure 4). The label \( \text{dist\_current} \) (shortened as \( d_c \)), is reduced during computation using the “minimum” operation. Consider a vertex \( v \) with proxies on hosts \( h_1 \) and \( h_2 \), where the master proxy is on \( h_1 \) and the mirror proxy is on \( h_2 \). The label \( d_c \) is initialized to \( \infty \) on both proxies. Say host \( h_2 \) sends values 10, 7, and 6 after executing its local rounds 1, 2, and 3, respectively. Say host \( h_1 \) receives all these values in the order 10, 6, and 7 at the end of its round 2. Host \( h_1 \), which still has \( \infty \) value for its proxy, reduces the received values one-by-one, yielding the update 6, and broadcasts this value to \( h_2 \). Host \( h_1 \) reduces its proxy value during computation to 5 and broadcasts it to \( h_2 \) after its round 3. Host \( h_2 \) receives both these values in the order of 5 and 6. The mirror proxy value on \( h_2 \) is 6 (because reset is a \textit{no-op} for minimum operation). If host \( h_2 \) had set the received values (in order) like in Gluon-Sync, then the final value of \( h_2 \) would be 6, which would be incorrect. Host \( h_2 \) instead reduces the received values one-by-one yielding the update 5. The proxies on both hosts are not updated thereafter and thus, both proxies have the same values.

An important point to note is that if the message is not empty, then Gluon-Sync and Gluon-Async send the same message. Gluon-Async thus retains the underlying advantages of Gluon-Sync. Gluon-Async supports any partitioning policy and performs bulk-communication, thereby utilizing Gluon’s communication optimizations that exploit structural and temporal invariants in partitioning policies [5]. Gluon-Async can be plugged into different CPU or GPU graph analytics systems to build distributed-memory versions of those systems that use BASP-style execution. As shown in Figure 2, communication between a GPU device and its host is a local operation. Gluon-Async treats this as a blocking operation like Gluon-Sync. While this can be made non-blocking too, it is outside the scope of this paper.

We showed that BASP-style execution can be used in Gluon-Async without any blocking or waiting operations among hosts. The messages, if any, will be eventually delivered. The key to this is that hosts must not terminate until there are messages left to be delivered. This requires non-blocking termination detection, which we explain next.

### C. Non-blocking Termination Detection

BASP-style execution requires a more complicated termination algorithm than BSP-style execution. We describe a non-blocking termination detection algorithm that uses snapshots to implement a distributed consensus protocol [25] that does not rely on message delivery order.

The algorithm is based on a state machine maintained on each host. At any point of time, a host is in one of five states: Active (\( A \)), Idle (\( I \)), Ready-to-Terminate\(_1\) (\( RT_1 \)), Ready-to-Terminate\(_2\) (\( RT_2 \)), and Terminate (\( T \)). The goal of termination detection is that a host should move to \( T \) if and only if every other host will move to \( T \). We describe state transitions and actions for ensuring this.

Hosts coordinate with each other by taking non-blocking snapshots that are numbered. When a host takes a snapshot \( n \), it broadcasts its current state to other hosts (non-blocking). Once a host \( h \) takes the snapshot \( n \), it cannot take the next snapshot \( n + 1 \) until \( h \) knows that every other host has taken the snapshot \( n \). In other words, before \( h \) takes the next snapshot \( n + 1 \), \( h \) should not only have completed the broadcast it
The first condition checks whether work was done in \( r \) while the other conditions check whether any work is still pending. These conditions must hold for \( h \) to take the next snapshot \( n + 1 \).

A host \( h \) is considered to be \textit{inspected} if it knows that all the hosts have taken the previous snapshot \( n \). This condition must hold for \( h \) to take the next snapshot \( n + 1 \). Similarly, a host \( h \) is considered to be \textit{affirmed} if (i) \( h \) has been inspected and (ii) it knows that all the hosts have taken the previous snapshot \( n \) from state \( RT_2 \) (that is, other hosts have also affirmed their readiness to terminate). This condition must hold for \( h \) to terminate.

Initially, every host is in state \( A \). Figure 6 shows the possible state transition on a single host. Table I shows the conditions that must hold for each state transition and the action, if any, taken after the state transition. No action is taken with transitions to states \( A \) and \( I \). When \( h \) transitions to \( RT_1 \) or \( RT_2 \), it takes a snapshot. When \( h \) transitions to \( T \), it decides to terminate (returns false in Line 26 in Figure 4). A host moves from \( A \) to \( I \) only if the host is inactive. If a host is not inactive, then it moves to \( A \) from the \( I \), \( RT_1 \), or \( RT_2 \) states. If \( h \) is inspected and is in \( I \), then it moves to \( RT_1 \). If \( h \) is inspected and is in \( RT_1 \), it moves to \( RT_2 \). If \( h \) is affirmed, then it moves from \( RT_2 \) to \( T \).

Consider an example with two hosts, \( h_1 \) and \( h_2 \). Initially, both of them initiate (dummy) snapshot \( n_0 \). When \( h_2 \) becomes inactive, it moves to \( I \). As both hosts initiated the previous snapshot \( n_0 \), \( h_2 \) moves to \( RT_1 \) and initiates the next snapshot \( n_1 \). Meanwhile, \( h_1 \) sends a message to \( h_2 \), becomes inactive, and moves to \( I \). As \( n_1 \) has ended, \( h_1 \) moves to \( RT_1 \) and initiates \( n_1 \). In the next round, \( h_1 \) detects that \( h_2 \) also has initiated \( n_1 \). Note that it would be incorrect for \( h_1 \) to terminate at this point, although both \( h_1 \) and \( h_2 \) initiated \( n_1 \) from \( RT_1 \).

Our algorithm uses two \( RT \) states to detect this, so \( h_1 \) moves to \( RT_2 \) instead of terminating and initiates the next snapshot \( n_2 \). During this time, \( h_2 \) received the message from \( h_1 \) which made it active and moved it to \( A \). Later, it moves to \( I \) and then \( RT_1 \) to initiate \( n_2 \). In the next round, \( h_2 \) observes that \( n_2 \) has ended, so it moves to \( RT_2 \) and initiates \( n_3 \). \( h_1 \) also observes that \( n_2 \) has ended and initiates \( n_3 \) while remaining in \( RT_2 \). Now, in the next round on both hosts, each host observes that \( n_3 \) has ended and that the other host has initiated \( n_3 \) from \( RT_2 \), so both hosts affirm to terminate and move to \( T \).

To implement our termination detection algorithm in GluonAsync (Line 26 in Figure 4), we use non-blocking collectives to take a snapshot. For the reduce and broadcast phases, we modify the communication substrate to send messages in \textit{synchronous} mode instead of \textit{standard} mode. In \textit{standard} communication mode of MPI or LCI [26], a send (call) may complete before a matching receive is invoked. Hence, both the sender and the receiver may become inactive and terminate while the message is still in-flight. In contrast, in \textit{synchronous} mode, a send is considered complete only if the receiver has initiated receive. Consequently, when a message is in-flight, either the sender or the receiver is in active state \( A \). Thus, \textit{synchronous} communication mode sends are necessary for our
termination detection protocol. Note that our protocol does not rely on the order of message delivery of Gluon or the underlying communication substrate such as MPI or LCI [26].

Note that goal of termination detection is that a host should move to $T$ if and only if every other host will move to $T$. We now argue how our termination detection algorithm satisfies this property. A non-active, non-terminated host $h$ can move back to state $A$ only if it receives data from another host – in this case, the inactive flag will become false. Since the program is correct, at least one host will not reach the $RT_2$ state until the final value(s) are computed (no false detection of termination). A host $h$ can reach the state $RT_2$ from $RT_1$ or $RT_2$ only if it is inspected and inactive, which means that $h$ did not update any labels and did not send nor receive data. If every host took the snapshot from $RT_2$, then no host computed, sent, or received data between two snapshots. Consequently, no host can receive a message and move to $A$ after that, so every host must terminate.

### IV. Experimental Evaluation

In this section, we evaluate the benefits of Bulk-Asynchronous Parallel (BASP) execution over Bulk-Synchronous Parallel (BSP) execution using D-Galois [5] and D-IrGL [5], the state-of-the-art graph analytics systems for distributed CPUs and distributed GPUs, respectively. Both these systems are built on top of a Gluon [5]. In this paper, we use the name Gluon-Sync to refer to these two systems. We modified D-Galois and D-IrGL BSP programs as described in Section III-A to make them amenable for BASP-style execution. As described in Sections III-B and III-C, we modified Gluon to support BASP-style execution for both systems, which we call Gluon-Async (source code is publicly available [27]).

We also compare the performance of Gluon-Async with that of Lux [6], which is a multi-host multi-GPU graph analytical framework that uses BSP-style execution; note that there are no asynchronous distributed GPU graph analytical systems to compare against. GRAPE+ [17] and PowerSwitch [14] are asynchronous distributed CPU-only graph systems, and we compare them with Gluon-Async.

We first describe our experimental setup (Section IV-A). We then present our evaluation on distributed GPUs (Section IV-B) and distributed CPUs (Section IV-C). Finally, we analyze BASP and BSP (Section IV-D) and summarize our results (Section IV-E).

We conducted all the GPU experiments on the Bridges cluster [28] at the Pittsburgh Supercomputing Center [29], [30]. Each machine in the cluster is configured with 2 NVIDIA Tesla P100 GPUs and 2 Intel Broadwell E5-2683 v4 CPUs with 16 cores per CPU, DDR4-2400 128GB RAM, and 40MB LLC. The machines are interconnected through Intel Omni-Path Architecture (peak bandwidth of 100Gbps). We use up to 64 GPUs (32 machines). All benchmarks were compiled using CUDA 9.2, GCC 7.3, and MVAPICH2 2.3b.

All the CPU experiments were run on the Stampede2 [31] cluster located at the Texas Advanced Computing Center. Each machine is equipped with 2 Intel Xeon Platinum 8160 “Skylake” CPUs with 24 cores per CPU, DDR4-2400 128GB RAM, and 66MB LLC. The machines in the cluster are interconnected through Intel Omni-Path Architecture (peak bandwidth of 100Gbps). We use 48 threads on each machine and up to 128 machines (6144 cores or threads). Benchmarks were compiled with GCC 7.1 and IMPI 17.0.3.

Table II shows the input graphs along with their key properties; twitter50 [32], [33] and friendster [34] are social network graphs; rmat27 is a randomized synthetically gener-
For Gluon-Sync and Gluon-Async, the partitioning policy is configurable as it uses the CuSP streaming partitioner [20]. Based on the recommendations of a large-scale study [21], we choose the Cartesian Vertex Cut (CVC) [9], [5] for all our experiments. We use LCI [26] instead of MPI for message transport among hosts.3

3sssp, clueweb12, GPUs uses Outgoing Edge Cut due to memory limits.

3Dang et al. [26] show the benefits of LCI over MPI for graph applications.

B. Distributed GPUs

Small graphs: Figure 7 shows the total execution time of Gluon-Async, Gluon-Sync, and Lux on small graphs using up to 16 GPUs. Missing points indicate that the system ran out of

4Both Gluon-Sync and Lux are BSP-style and use the same algorithm.
memory (except for Lux with cc on rmat27 using 16 GPUs, which failed due to a crash). The major trend in the figure is that both Gluon-Async and Gluon-Sync always outperform Lux and scale better. It is also clear that Gluon-Async and Gluon-Sync perform quite similarly. In some cases, Gluon-Async is also noticeably slower (pr on twitter50). We do not expect Gluon-Async to perform better than Gluon-Sync for low-diameter graphs like these because most benchmarks in Gluon-Sync execute very few (< 100) rounds for these. We will analyze this later using larger graphs (Section IV-D). Nevertheless, both Gluon-Async and Gluon-Sync are on average ∼ 12× faster than Lux.

Large Graphs: Figure 8 shows the speedup in total execution time of Gluon-Async over Gluon-Sync for large graphs using up to 64 GPUs (Lux runs out of memory for all the large graphs, even on 64 GPUs). Missing points indicate that either Gluon-Sync or Gluon-Async ran out of memory (almost always, if one runs out of memory, the other also does; only in a couple of cases, Gluon-Async runs out of memory but Gluon-Sync does not because Gluon-Async may use more communication buffers). 64 GPUs are insufficient to load wdc12 as input, partition it, and construct it in memory; so both Gluon-Sync and Gluon-Async run out of memory. It is apparent that Gluon-Async always outperforms Gluon-Sync for large graphs. We observe that the speedup depends on both the input graph and the benchmark. Typically, speedup is better for clueweb12 and wdc14 than gsh15. The speedup is also usually lower for pr than for other benchmarks. We also see that in most cases, the speedup of Gluon-Async over Gluon-Sync increases with an increase in the number of GPUs. This indicates that Gluon-Async scales better than Gluon-Sync. For high-diameter graphs on 64 GPUs, Gluon-Async is on average ∼ 1.4× faster than Gluon-Sync.

C. Distributed CPUs

Small graphs: Table III shows the total execution time of PowerSwitch, GRAPE+, Gluon-Sync, and Gluon-Async for friendster with 192 threads. Note that Gluon-Sync and Gluon-Async used machines on Stampede, whereas PowerSwitch and GRAPE+ used machines on a different HPC cluster. Similar to GPUs, the performance differences between Gluon-Async and Gluon-Sync are negligible because friendster is a low-diameter graph. Although both GRAPE+ and PowerSwitch are asynchronous systems, they are much slower than Gluon-Sync and Gluon-Async. Both Gluon-Sync and Gluon-Async are on average ∼ 2.5× and ∼ 9.3× faster than GRAPE+ and PowerSwitch, respectively. This shows that a well-optimized existing bulk-synchronous system (Gluon-Sync) beats the existing asynchronous systems and that it is challenging to reap the benefits of asynchronous execution. Gluon-Sync uses Galois [23] computation engine and Gluon [5] communication engine. Both have several optimizations that help Gluon-Sync outperform PowerSwitch and GRAPE+. It is not straightforward to incorporate these optimizations in PowerSwitch and GRAPE+ due to the way they perform asynchronous communication. Gluon-Async introduces a novel way for asynchronous execution while retaining all the performance benefits of on-device computation engines like Galois and IrGL [39] and the inter-device communication engine, Gluon. While Gluon-Sync and Gluon-Async perform similarly for small graphs, we show that on large graphs, Gluon-Async can be much faster than Gluon-Sync.

Large graphs: Figure 9 shows the speedup in total execution time of Gluon-Async over Gluon-Sync for large graphs using up to 128 Skylake machines or hosts. Missing points indicate that either Gluon-Sync or Gluon-Async ran out of memory. The trends are similar to those on GPUs. The speedup depends on both the input graph and the benchmark. Gluon-Async mostly outperforms Gluon-Sync; its performance is similar or lower than that of Gluon-Sync on 64 or fewer hosts in some cases for pr or in some cases for the input gsh15. The speedup of Gluon-Async over Gluon-Sync increases with the increasing number of hosts indicating that on distributed CPUs also, Gluon-Async scales better than Gluon-Sync. For high-diameter graphs on 128 CPUs, Gluon-Async is on average ∼ 1.6× faster than Gluon-Sync.

D. Analysis of BASP and BSP

Using Gluon-Async and Gluon-Sync, we now analyze the performance difference between BASP-style and BSP-style execution, respectively, on both distributed GPUs and CPUs. Specifically, we focus on: (1) why the difference arises (load imbalance), (2) where the difference exists (idle time), and (3) how the difference manifests itself (rounds executed).

Load imbalance: Table IV shows the number of rounds executed by benchmarks in Gluon-Sync for the large graphs. It can be observed that higher diameter graphs are likely to execute more rounds, except for pr. We next measure the load imbalance by calculating the total time spent by each host in computation and determine the relative standard deviation (standard deviation by mean) of these values. Figures 10(a) and 10(b) presents these values for Gluon-Sync as a box-
plot\(^5\) for all the number of devices (CPUs or GPUs) for each benchmark and input graph on Bridges and Stampede, respectively. Each point in a box-plot is a value for a distinct configuration of the number of devices (CPUs or GPUs) for that benchmark and input graph. The load imbalance and the number of rounds can be used to tell whether Gluon-Sync can benefit from switching to BASP-style execution. As cc on gsh15 is well balanced and executes very few rounds, it does not benefit much from BASP-style execution. In contrast, benchmarks using clueweb12 are more imbalanced and benefit significantly from BASP-style execution, even if it executes very few rounds like in cc. For high-diameter graphs, load balance is difficult to achieve in efficient data-driven graph applications [11] because different subsets of nodes may be updated in different rounds. We show that Gluon-Async circumvents this by using BASP-style execution.

**Idle time:** We define busy time of a host as the time spent in computation, serialization (for packing messages to be sent), deserialization (for unpacking and applying received messages), and communication between host and device. The rest of the total time is the idle time; in BASP, idle time includes the time to detect termination. Different hosts can have different busy and idle times (stragglers have smaller idle times), so we consider the minimum and maximum across hosts. Figure 11 show the breakdown of execution time into minimum busy time, minimum idle time, and the difference between maximum and minimum idle time. As expected, BSP has high maximum idle time due to load imbalance and BASP reduces idle time, which is one of the main advantages of having bulk-asynchronous execution. However, this reduction in idle time could lead to a corresponding increase in busy time because the host could be doing redundant or useless work by operating on stale values instead of being idle. This depends on the input graph and the benchmark. In some cases like pr, the busy time increases even though the idle time is reduced. In most other cases, the busy time does not increase by much. Nevertheless, it is clear that the difference between BASP and BSP is in the idle time, and the total execution time will be reduced only if the idle time is reduced without an excessive increase in busy time.

**Rounds executed:** All hosts execute the same number of rounds in BSP (Table IV), whereas different hosts may execute different numbers of local rounds in BASP. The minimum

---

\(^5\)The box for an input graph and benchmark represents the range of 50\% of these values for that input graph and benchmark; the line dividing the box is the median of those values and the circles are outliers.
routines executed in BSP and BASP are shown on each bar in Figure 11. We use the minimum local rounds among hosts to estimate the critical path in the execution. We count the number of edges processed (locally) on each host and use the maximum among hosts to estimate the work done in the execution. Figure 12 presents the correlation between the speedup in execution time, the increase or growth in the work done (maximum local work items or edges processed), and the reduction in the critical path (minimum local rounds). Each point is a value for a distinct configuration of benchmark, input, and number of devices (CPU or GPU); we have omitted outliers. Red (closer) points have lower growth in the work done and higher points (taller lines) have more reduction in the critical path. Although the minimum number of local rounds in BASP may be smaller than that of BSP, the maximum number of local rounds in BASP may be higher because the faster hosts need not wait and may execute more local rounds. Instead of waiting after every round in BSP, faster hosts in BASP may execute more rounds. Consequently, faster hosts could make more progress and send updated values to the stragglers or slower hosts. The straggler hosts receive these updated values before they move to the next round, saving them from doing redundant work using stale values. Thus, straggler hosts doing fewer local rounds leads to faster convergence in BASP.

E. Summary and Discussion

Table V compares the performance of Gluon-Sync and Gluon-Async using the best-performing number of CPUs and GPUs. Both Gluon-Sync and Gluon-Async mostly scale well, so their best performance is usually on the maximum number of CPUs or GPUs we evaluated. For low-diameter graphs, Gluon-Async and Gluon-Sync are comparable. For high-diameter graphs, Gluon-Async is on average ~ 1.5× faster than Gluon-Sync. The speedup varies depending on the
benchmark, the input, and the scale (number of devices). The speedup is typically best for high-diameter graphs at scale. This is similar to what has been observed for asynchronous execution on CPUs [23] or GPUs [40]. Thus, Gluon-Async helps scaling out large real-world graph datasets.

V. RELATED WORK

Asynchronous Distributed Graph Analytics Systems. The popularity of the bulk-synchronous parallel (BSP) model [10] of computation has led to work that improves its performance by improving the underlying asynchrony and reducing the wait time. GraphLab [12] and PowerSwitch [14] systems use their gather-apply-scatter model along with distributed locking for non-blocking, asynchronous execution. None of the other systems, including Gluon-Sync, use locks. Systems like Aspire [13], GRACE [15], Giraph++ [16], and ASYMP [41], which are based on asynchronous parallel (AP) model, avoid delaying the processing of the already arrived messages. GiraphUC [42] proposes the barrierless asynchronous parallel (BAP) model that uses local barriers to reduce the message “ staleness” and overheads due to global synchronization. While GiraphUC is lock-free and asynchronous, it blocks during synchronization until it receives the first message (from any host). Most recently, Fan et al. [17] show that the Adaptive Asynchronous Parallel (AAP) model used in their GRAPE+ system can be used to dynamically adjust the relative progress of different worker threads and reduce the stragglers and stale computations. Similarly, Groue [40] proposes an asynchronous system, but it is limited to a single node system.

Most of these existing systems either perform fine-grained synchronization or do not support general partitioning policies. None of them can be extended for vertex-cuts without significantly increasing the communication cost; i.e., some of the communication optimizations [5] would need to be dropped for such an extension (to elaborate, GRAPE+ is the only one that can support vertex-cuts without using distributed locks, but they send an updated value from a proxy directly to all the other proxies instead of reducing updated values to a master proxy and broadcasting the result to mirror proxies, resulting in more communication volume and messages). Consequently, prior asynchronous systems do not perform as well as the state-of-the-art BSP-style distributed systems [4], [5]. Moreover, none of the prior asynchronous systems can be extended trivially to support execution on multi-host multi-GPUs.

In contrast, we propose a Bulk-Asynchronous Parallel (BASP) model for both distributed CPUs and GPUs in which the threads potentially never wait and instead continue to do local work if available without explicitly waiting for the communication from other hosts. Our redesign of reduce and broadcast communication phases enables removing synchronization while exploiting bulk-communication.

Bulk-Synchronous Distributed Graph Analytics Systems. There have been many works that support graph analytics on distributed CPUs [2], [3], [4], [5], [43] or GPUs [5], [6] in the Bulk-Synchronous Parallel (BSP) model. Our proposed approach targets wait-time reduction in graph applications by exploiting the underlying asynchrony in codes written in BSP models, and it targets distributed CPU and GPU systems.

VI. CONCLUSION

This paper presented a novel programming model called BASP that takes bulk-communication from BSP models and continuous compute from asynchronous models to improve overall runtime of programs. We showed that it is easy to adapt BSP programs for BASP execution by modifying programs in D-Galois and D-IrGL, the state-of-the-art distributed graph analytics systems for CPUs and GPUs, respectively. Both these systems use the Gluon substrate for communication. We modified Gluon to support BASP and build the first asynchronous distributed and heterogeneous graph analytical system, Gluon-Async (source code is publicly available [27]). Gluon-Async retains the benefits of Gluon, so it can handle arbitrary partitioning policies and can be used to extend existing CPU or GPU graph analytical systems for distributed and heterogeneous execution. Our evaluation shows that on real-world large-diameter graphs at scale, BASP programs are on average ~ 1.5x faster than D-Galois and D-IrGL, respectively. Gluon-Async also scales better than them.
